Water Delivery Schedules and Crop Water Needs

Data from the KAFA'A farm survey covering the 2002-2003 crop season was used earlier to assess the comparative crop water use efficiency of irrigation water used in the Jordan Valley by crop type and by zone.

Cropping patterns among survey sample farms were matched with crop water requirements derived using evapotranspiration data and crop-specific coefficients to generate estimates of the value of production per 1,000 cubic meters of irrigation water. Preliminary results indicated that vegetable crops generate higher values of production per unit of water than either bananas or citrus crops. They also showed that crop water use efficiency in the Central Jordan Valley; where vegetable production predominates, was higher than in the North Jordan Valley where citrus is the major crop.

The validity of these findings has been called into question because crop water requirements have not been established specifically for the Jordan Valley areas. The theoretical values of water consumption requirements thus generated for all three groups of crops exceeded significantly actual water delivered by the Jordan Valley Authority to farmers in the Valley.

The attempt is made in this report to reassess the crop water use efficiency analyses using the regulation for irrigation water delivery estimates provided by the Jordan Valley Authority.

Tables 1-a, 1-b, and 1-c are the schedule of water delivery that the JVA uses to determine how much water to give to farmers, depending on the month and the type of crop. Three crop categories are given – bananas, citrus, and vegetables. For each category JVA stipulates how many millimeters of water to provide the farms for each type of crop per day (bananas, citrus or vegetables). Table 1-d condenses the same information for the three zones in an easy to read format. Bananas in the North Jordan Valley, for example, require 7 mm per day in the hot summer months, but only 3 mm per day in the cool winter months (See Table 1-d and Figure 1-a). Figures 1-b and 1-c provide the same information for the Center and South Jordan Valley.

Vegetable crops occupy the land only a few months each season. In Tables 1-a to 1-c, two separate seasons – autumn and spring – are considered. We note however that in summer months the allowance for vegetables drops to 1 mm per day while for both citrus and bananas water allocation reaches maximum levels. This occurs because JVA is discouraging vegetable production in summer months and reduces vegetable water allowance to a minimum, which most farmers use for soil sterilization. This part of the analysis is introducing a change in the water allocation for vegetables, reflecting a situation of actual needs of crops during the months they are on the ground.
Table 2-a is the same as Table 1-d for bananas and citrus crops but differs in the columns for water allowance for vegetables. We have set water deliveries of all vegetables at the maximum that JVA allows -- 2 mm per day during the entire year. This might be

overestimating actual needs of vegetable crops, especially on the cooler winter months. Results from subsequent analyses thus incorporate a bias against vegetable crops because their water needs are probably overstated. *Table 2 is designed to be interactive, so that analysts can modify any or all individual cell entries in the table, and all subsequent analyses automatically adjust accordingly.*

Tables 3-a through 3-c, also derived from information kindly provided by JVA (water allowance regulation) for this study, provide typical crop calendars for the main crops in the Jordan Valley. The shaded cells indicate the months when each crop occupies the land, and the numbers in the background indicate cubic meters of irrigation water allocated per dunum in each month. The season's total water allocated is merely the sum of the monthly entries in each row. Separate data are provided for the North, Center, and South Jordan Valley in Tables 3-a through 3-c and Figures 3-a through 3-c, respectively. Bananas water allocation is the highest (about 1,500 m3 per year per dunum), and citrus come second at about 1,000 m3 per year per dunum. For most vegetable crops annual water allocations range between 200 and 500 m3 per dunum, depending on the specific crop and on which months they occupy the ground.

Adjustment for Rainfall

One of the possible reasons for discrepancy between estimated crop water allocation and the actual volumes of water delivered and billed by JVA is that in months when there is significant precipitation JVA delivers significantly less irrigation water to open field crops, including citrus orchards. In the North Jordan Valley where the precipitation is highest, several months might pass without JVA delivering water to some farms.

According to rainfall information from the Jordan Meteorological Department, over a period of 20 years the North Jordan Valley receives on average 252 mm of effective precipitation in a season, compared with 222 mm in the Center Jordan Valley, and only 57 mm in the South end of the Valley. Effective precipitation is defined as the portion of rainfall that is usable by plants, after discounting for runoff and other losses.

The rainy season in Jordan is highly concentrated in the winter months. The first few rains start in October and continue through early June, but the bulk of precipitation occurs between December and March. Table 2-b provides the percentages of total rainfall in different months. These percentages were obtained from Jordan Meteorological Department data as they appear in an article by Sahar Aloul in The Jordan Times of Monday, November 8, 2004. The same percentage distribution values for the Jordan Valley were used, even though the overall distribution corresponds to rainfall in Jordan. When specific values can be obtained for the three zones in the Jordan Valley, those values can be inserted into Table 2-b to arrive at more refined estimates.

Between December and March, rainfall makes significant contributions to satisfy the actual crops water needs. In North Jordan Valley, rains provide 45 mm of effective precipitation in December; 58 mm in January, 53 mm in February, and 48 mm in March.

These values are sufficient for citrus and open field crops during the winter months, when evapotranspiration is at its minimum.

Therefore the crop water needs (better defined as *JVA needed allocations*) estimates are adjusted to account for the contribution of effective precipitation. Crops grown under greenhouse conditions do not benefit from rain because the plastic houses do not normally collect and store rainwater for crop use. JVA water allocations of open field crops and tree crops are therefore adjusted accordingly, to account for rain, depending on the month when those crops are on the ground. This is done and reflected in Tables 3-a, 3-b, and 3-c for the main crops and farming systems in the North, Center, and South Jordan Valley, respectively. Figures 3-a, 3-b, and 3-c also take the effect of rainfall into account. The cumulative values for water allocations during the season therefore reflect the supplemental crop water allocation needs to be provided.

The new estimates of water allocation needed for most crops are therefore reduced across the board, except for vegetables grown in greenhouses and multi-spans. Citrus in the North only require 751 m3 per dunum allocation, instead of the 1,003 m3 when rainfall was not taken into account. The values for bananas and open field vegetables are also reduced by corresponding amounts.

The survey questionnaire did not ask specifically when fields were planted and harvested. Then the averages of the annual values in Tables 3 for the alternative timing schedules were used. The complete set of crop water allocation needs for the valley is shown in Table 4. Some crops in the cropping pattern of the survey sample farms do not appear explicitly in Tables 3-a to 3-c. In those cases the estimates of water allocation needs for similar crops are used.

Table 5 consolidates the new water allocation needs estimates with the crop information from each survey sample farm, into a single spreadsheet labeled ZUCCFAV that stands for “zone, unit, crop, category, farming type, area, and value.” This is a large file with nearly 2,000 entry lines, one for each crop in each farm, but only an excerpt of that table is printed as an example.

Value per 1000 cubic meters of Water

Table 6 summarizes the total area, value of production, and water allocation needs for each crop in the survey sample in the Jordan Valley, sorted out by crop category so that all citrus appear together, and all vegetables are separate. From those values it is possible to compute the per dunum values for value and gross revenue less deductions for initial investments, and water allocation needs. It is also possible to compute the value of production per 1000 m3 of irrigation water, as well as the gross revenue less deductions for initial investment.

Tables 7-a, 7-b, and 7-c depict the cropping pattern in the North, Center and South Jordan Valley, and Figures 7-a, 7-b, and 7-c show the same information in a graphic mode.

These cropping patterns are already well known and described in a prior KAFA'A report. The values presented here are slightly improved because some anomalous cases were removed from the analysis. Citrus crops predominate in the North, with the main fruits being clementine, sour orange, and navel orange. Vegetable production dominates the Center Jordan Valley, with tomato being the principal crop, followed by potato, cucumber and zucchini. Tomato and eggplant predominate in the South, but zucchini, lettuce, maize and peppers are also present.

Crop water allocation needs and consumption are shown in Table 8, also derived from tabulations using data in Table 5. Clementine is by far the crop using the largest volume of water, followed by sour oranges, navel oranges, and bananas. Among vegetables, tomatoes use the largest quantity of irrigation water; followed by cucumbers, eggplants, zucchini, and potatoes.

Several simple tabulations are consolidated in Table 9 to generate Figures 9-a to 9-f. The value of production per dunum are illustrated by the four leftmost columns in Figure 9-a. Bananas are the most valuable crop per dunum, 1,036 JD per dunum. Vegetable crops come next with an average of 603 JD per dunum, and citrus crops with an average of 478 JD per dunum. (Note: the values of "other trees" comprise an assortment of fruits including olives, grapes, pomegranate, date palms, guavas, but there are too few observations in the sample and the group is too diverse for being properly viewed as a group). The four columns in the middle of Figure 9-a represent the water allocation needs of the four crop categories that result in bananas needing 1,447 m3 per dunum per year, compared with 786 m3 for citrus crops, and 260 m3 for vegetable crops. Note that effective rainfall has been already subtracted; these figures do not include water contributed by rainfall, only the supplemental irrigation water provided by JVA.

Value of production per 1000 cubic meters of irrigation water by crop category are shown by the four rightmost columns in Figure 9-a: Bananas generate 716 JD per 1000 m3, slightly more than citrus crops on average, 608 JD per 1000 m3. Vegetables crops, however, generate a remarkable value of production of 2,320 JD per 1000 m3, mainly because it only uses one sixth of the water needed by bananas, and three times less than citrus. These returns per unit of water are summarized in Figure 9-c.

Another way of viewing the same results is in Figure 9-b. Citrus crops occupy 37 percent of the land, use 56 percent of the irrigation water, and contribute 31 percent of the value of farm production. By contrast, vegetable crops occupy 57 percent of the land, use only 29 percent of the water, but contribute 61 percent of the value of production. The relative crop water use efficiency of vegetables in terms of value of production per unit of water is manifest.

A similar pattern can be discerned when water used is disaggregated by zone instead of crop category. Figure 9-d shows the value of production per dunum in North – 420 JD, Center – 852 JD, and South – 371 JD. In contrast, water allocation needs per dunum are highest in the North – 633 m3 per year, while the Center – 389 m3, and the South – 394 m3, consume over half as much. The net result is that crop water use efficiency in the

North is only 663 JD per 1000 m3 of irrigation water, while in the Center the same amount of water generates 2,189 JD, and in the South 941 JD. These results clearly reflect the predominance of citrus crops in the North and of vegetable crops in the Center. The relative efficiencies in crop water use by zone are summarized in Figure 9-f.

The North zone Valley consumes over 60 percent of the irrigation water in the Jordan Valley but contributes only 37 percent of the value of farm production (see Figure 9-e). By contrast, the Center zone consumes 26 percent of the water to generate 52 percent of the value of production. The South occupies an intermediate position, consuming 13 percent of the water and contributing 11 percent of the value of production.

Water Allocation Needs and Water Bills

The above analyses were based on estimates of crop water allocation needs derived from JVA's schedule of water deliveries for the main crop categories in the North, Center, and South zones of the Jordan Valley. JVA officers wonder to what extent these water allocation needs estimates correspond to actual water deliveries to farm units in the Valley.

To get irrigation water, farm owners are required to come in person to the local JVA stage office before the start of each month to request how many days per week of water are needed. These requests are monitored by JVA to ensure that they correspond to the needs of the farms, based on the area planted and growing stage of each crop and climatic conditions at the time. JVA schedules pumping days and hours at a given water pipeline depending on the requests submitted by farmers served by the line. The ditch rider is the person responsible for ensuring compliance by farmers with the schedule. Farmers requesting two days a week are fined 150 JD if they open their FTA valves on days other than those requested and authorized. Most farmers simply request the maximum number of days.

Farmers are billed by JVA according to the estimated volume of water delivered to each farm. These estimates are made based on the number of days requested by farmers in a given line, prorated by the areas in each crop category in the farm, and the total volume of water pumped through the water line in that month. Water flow meters in each FTA are not really used to measure the volume of water received by each farm. JVA has lost confidence in flow meter measurements because they suspect some farmers tamper with the mechanism. Too many meters are not in working order and JVA has insufficient logistic and technical capabilities to keep up with the repair demands. Farmers often complain that their water bills bear little resemblance to actual water received, especially farmers at the end of the line where the pressure is lower than at the head.

JVA billing structure tariff rates at present are 8 fils for the first 2,500 cubic meters in a month, 12 fils for the next 1,000 m3, 20 fils for the next 1,000 m3, and 35 fils for any volume above 4,500 m3 per month. (For comparison purposes, the rates reportedly paid by Amman residents average over 400 fils per cubic meter). A typical 30 dunum farm

using 2 mm per day would consume 1,800 cubic meters per month (1,800 = 2*30 days*30 dunum), and therefore be eligible for the lowest rate of 8 fils/m3.

Water costs represent a very small share of the value of the crop. The water bill for a citrus farmer who requests an average of about 1,000 m3 per dunum per year, would only amount to 8 JD per dunum per year, less than 2 percent of the value of the crop, estimated between 400 and 500 JD depending on the specific citrus fruit.

What relationship do water bills have with the water needs of the farms?

The answer to this question would allow us to judge the validity of the water allocation needs estimates done above in this report. Ideally, a close correspondence between the water needs of a farm unit and the total water bill received for the season would verify that estimates of water allocation needs based on JVA's water delivery schedules are effectively applied in practice.

The Jordan Valley Authority kindly provided KAFA'A the record of monthly water bills to most of the survey sample farm units in the Jordan Valley. These records are summarized in Table 10, which provides total water volume billed per calendar year and per agricultural year (August to July). The column of most interest is for the 2002-2003 season, covering the same period as the farm survey.

Table 11 consolidates information for each sample farm unit, including the estimate of water allocation needs based on the cropping pattern, and the JVA water bill for the 2002-2003. Figure 11 is a scatter diagram, each sample farm represented by a dot, with water allocation needs in the horizontal axis and water bills on the vertical axis. Dots close to the diagonal line show a very good match between water bills from JVA and water allocation needs as estimated using water delivery schedules. Dots above the diagonal correspond to farms that are billed for more than they need, and dots below the diagonal are farms receiving less water than allocation needed. (Note: it is assumed here that water bills are accurate reflections of water delivered to farms).

It is clear from the chart that for most farms, there is little correspondence between water allocation needed and the volume in the water bills, because most dots are far from the diagonal line. The correlation coefficient between water allocation needs and bills is only 0.34 (R-Square 0.11), indicating a week relationship between the two values. Most of the variation in water bills among farms cannot be attributed to the irrigation allocation needs. The average farm bill is for 16,950 m3 with a standard deviation of 9,184; the average estimate of water allocation needs per farm is 16,022 m3 and a standard deviation of 12,241 m3. Thus, the total amount of water billed roughly matches the volume allocation needed, but the deliveries among farms do not match their particular needs.

It would be of some interest to determine whether farms above the diagonal – those receiving more water than needed – share some common characteristics. As a first approximation, we distinguish between vegetable farms and those producing citrus and

other tree crops (including bananas). Vegetable farms are those where more than half of the area is planted to vegetable crops. Figure 12 uses circles to distinguish vegetable farms from the diamonds used for tree farms. It is remarkable that most of the vegetable farms are congregated to the left of the graph and mostly above the diagonal line, while most tree farms are below the diagonal. This indicates that most citrus and other tree farms are billed for less water than allocation needed, while vegetable farms are billed for more water than allocation needed. In other words, most vegetable farms are getting more water than their allocation needs, while the contrary is true for most tree farms. There is potential water saving opportunities among vegetable farms that could be tapped if there were proper incentives to farmers to do so.

Another possible line of inquiry is to relate the amount of water billed (and supposedly delivered) with the actual number of dunums planted to bananas, citrus, vegetables, and other tree crops. This is accomplished using the standard statistical regression procedures available in the spreadsheet. For each farm unit in the Jordan Valley survey sample we regress the 2002-2003 water bill against the areas planted to these four crop categories. We have a total of 383 farms for which we have a complete set of data. Table 13 shows the summary results of the regression analysis and Figure 13. The following equation was obtained through the least squares procedure used in the regression analysis:

Water bill in m3 = 867 * banana dunums
+ 487 * citrus dunums
+ 640 * other trees dunums
+ 446 * vegetable dunums

The explanatory power of this equation to predict actual water bills is only 12 percent (R-Square = 0.12), but the crop coefficients are all highly significant. For each banana dunum JVA charges on average for 867 m3; for citrus trees 487 m3, and for vegetables 446 m3. These values suggest that water deliveries for citrus are only slightly higher (487 m3) than for vegetables (446 m3), and that bananas get only double (867 m3) the amount of water than say, potatoes (446 m3). How much these values correspond to actual water deliveries remains an open question. Most (88 percent) of the variation in water bills remain unexplained.

A slight improvement in explanatory power is shown in Table 14 and in Figure F 14. Regression analysis is also used to estimate another equation in which the intercept coefficient is not zero:

Water bill in m3 = 10,408
+ 509 * banana dunums
+ 214 * citrus dunums
+ 352 * other-trees dunums
+ 187 * vegetables dunums.

The explanatory power is raised to 14 percent (R-Square = 0.14) and the crop coefficients remain strongly significant; but most (86 percent) of the variation in water bills is not explained by the crop pattern. This equation says that on average a farm was billed for

10,408 m3 for the 2002-2003 season, plus 509 m3 for each dunum in bananas, plus 214 m3 for each dunum in citrus, plus 352 m3 for each dunum in other fruit trees, and 187 for each dunum in vegetable crops. The difference in the 2002-2003 season water bills for citrus (214 m3) and vegetables (187 m3) is therefore minimal (27 m3). Seemingly, the water bills reflect little difference in water delivered to citrus farms and to vegetable farms, the two major crop categories. Water delivery to farms apparently bears little resemblance to the water allocation needs that JVA uses to estimate water delivery schedules.

Adjustments for Initial Investments

One of the main findings from the KAFA'A Jordan Valley Farm Survey has been that water used in vegetable crops on average yields higher value of production per ton (cubic meter) of water than other crop categories.

This overall finding has been questioned on several grounds: First, vegetable production includes a diversity of farming systems, from open fields to green houses, and multi-span structures. Second, the value of production neglects to take into account the high investment required to establish green houses and multi-span structures to produce winter vegetables in the Jordan Valley. This section attempts to address these concerns by introducing rough estimates of initial investments required by each crop category and farming system.

Table 15 summarizes preliminary calculations to estimate appropriate deductions from the value of production to account for amortization of large investments in crop production. These include greenhouses for vegetables but also estimates of establishment costs for citrus orchards and banana fields.

Current costs for greenhouses in 2004 were about 1,300 JD for the metal frames and 300 JD for the plastic covers. The metal frames can be used over a period of 10 years but the plastic covers only last 3 years. Amortization rates computed with a 12 percent rate of interest amount to 230 JD for the frames and 125 JD for the plastic cover, for a combined yearly amortization payment of 355 JD per dunum. The cost of greenhouses has increased significantly in the past couple of years. In 2002-2003, the crop seasons covered in the farm survey, the reported cost of frames was 1,000 JD and the plastic covers 200 JD. Amortization cost were only 177 JD for the frames and 83 JD for the plastic, for a combined annual amortization cost of 260 JD. This cost is then subtracted from the value of production in the survey data for vegetables plots using greenhouses or multi-span technology. Greenhouses can also be rented in the Jordan Valley and the reported rates per season vary between 250 and 300 JD, roughly corresponding to the estimated amortization payment.

There are no readily available estimates on the cost of establishment of citrus orchards in the Jordan Valley. Commercial production in citrus begins in the fifth year. Farmers need to advance the initial cost of purchasing and planting the trees, setting up the irrigation system, and then nurturing the orchard for the next four years. Preliminary rough estimates of annual outlays per dunum are: 303 JD for the first year, and 114 JD for each of the following three years. At the beginning of the fifth year, these outlays plus accruing interest charges at 12 per cent add up to a cumulative investment of 908 JD per dunum. This investment is amortized over an estimated 20 year productive life span for the orchard. An annual amortization costs for citrus orchards is 122 JD is therefore subtracted from the value of production of all citrus varieties in the farm survey.

Banana trees do not require as long a period before they begin production in the second year. For purposes of this exercise and in the absence of better estimates, we estimate an

initial establishment cost for bananas of 483 JD per dunum. This initial cost, amortized over a period of 10 years at 12 percent interest rate, requires an annual amortization payment of 85 JD per dunum.

No information is easily available about establishment cost for other fruit trees, such as for guava, olives, date palms, grapes, and pomegranate. The same annual cost as for citrus is assumed for all other fruit trees, as a preliminary assumption for the purposes of this exercise, but better estimates should be substituted as they become available.

A new variable – Revenue – is introduced into the survey database ZUCCFAV (See Table 5), computed as the value of production less the above deductions for initial investment costs, depending on the crop category and farming system. We are then able to carry out the same analyses done before for value of production, but now using the Revenue column to bring all crops into comparable bases as annual vegetable crops on open fields where only current season costs are covered.

Table 16 comprises several tabulations using the Revenue variable (value of production less deductions for initial investments) and serve to generate a new set of accompanying figures to illustrate the comparative water use performance of crop categories. Figure 16-a shows the gross Revenue values per dunum of bananas (951 JD), citrus (356 JD), other trees (163 JD), and vegetables (569 JD). In the same Figure 16-a are shown the water allocation needs values calculated earlier in this report, after making allowance for the contribution of rainfall: 1,447 cubic meters per dunum of bananas, 786 for citrus, and 260 m3 for vegetables. From these two sets of figures we can compute the Revenue per 1000 cubic meters of water delivered by JVA that are shown in the right most set of columns in the graph: 657 JD for bananas, 453 JD for citrus, and 2,192 JD for vegetables. Once again, the revenue per unit of water used in vegetables is five times higher than in citrus, and three times higher than in bananas.

The relative magnitudes of gross Revenue per unit of water in vegetables over citrus and bananas are higher than those when the Value of Production was used. The obvious explanation is that the 260 JD deduction is only about ten percent of the value of production in greenhouse vegetables, while the deduction of 122 JD for citrus is about one third of the value per dunum of citrus.

Adjustments for Farming System in Vegetables

Another critique of the comparative analyses of water efficiency use in different crop categories is that the vegetable category combines both open field and greenhouse vegetables and that obscures the comparison in favor of that category. It should be of interest of see how open field vegetables perform as a separate group from greenhouse vegetables. Other tabulations included in Table 16 are used to obtain disaggregated values for vegetables in the four farming systems used in the Jordan Valley: 1 for open field, 2 for plastic tunnels, 3 for greenhouses, and 4 for multi-span structures.

Figure 16-b shows the areas planted in the survey sample farms to bananas (394 dunums), citrus (4,804 dunums), other trees (434 dunums), and vegetables (7503 dunums) in four farming systems. Open fields are by far the predominant farming system used for vegetables (6,456 dunums), followed by greenhouses (867 dunums). Only 97 dunums of vegetables were reported in multi-spans and 83 dunums in plastic tunnels.

Values of Production per dunum are shown in Figure 16-c for each crop and farming system category, while gross Revenues excluding deductions for initial investment are show in Figure Y4. The values of production for bananas, citrus and other trees are already known: 1,036 JD, 478 JD, and 284 JD per dunum, respectively. Values of production for vegetable vary greatly from 346 JD for open fields, 640 JD for plastic tunnels, to 2,371 JD for greenhouses and 1,836 JD for multi-spans. Plastic greenhouses clearly contribute to a four to six fold increase in value per dunum over open fields and simple plastic tunnels.

After excluding deductions for initial investment, gross Revenue per dunum of vegetables are reduced significantly for greenhouses and multi-spans to 2,110 JD and 1,575 JD respectively (See Figure 16-d). The values for open field and simple plastic tunnel remain unchanged at 346 JD and 640 JD, respectively. Revenue per dunum of bananas and citrus are also reduced to 951 JD and 356 JD respectively. For citrus, a deduction for initial investment of 122 JD from the value of production of 478 LD represents a reduction of 25 percent. By contrast, subtracting 260 JD for amortization of infrastructure from the 2,371 JD value of production of greenhouse vegetables only represents a reduction of 11 percent. Note: these revenue comparisons are valid for evaluating future returns to water use in different crop categories. Once orchards are established, sunk costs lose relevance because they cannot be recovered if citrus orchards were to be replaced by other crop types.

Figure 16-e recalls estimated water delivery allocation needs after allowance for rainfall for bananas (1,447 m3 per dunum), citrus (786 m3), and other trees (900 m3). The new values for vegetables are 236 m3 per dunum in open fields, 409 m3 for plastic tunnels, and 408 m3 for greenhouses, and 416 m3 for multi-spans. The higher values for the latter reflect the longer life span of vegetables grown under greenhouse conditions.

It is now possible to compare returns per unit of water by crop and farming systems category, using both the value of production and revenue after deductions for initial investment costs. Figure 16-f depicts graphically those values for 1000 cubic meters of water. For bananas, revenue per 1000 m3 dropped from 716 to 657 JD. For citrus returns declined from 608 JD in value terms to only 453 JD after deductions for cost of establishing the orchard. For vegetables in open field and under simple plastic tunnels returns per 1000 m3 are 1,470 and 1,562 JD respectively, three to five times the revenue for citrus. Returns per 1000 m3 in greenhouse vegetables, and in multi-spans are remarkably high: Value of production of 5,811 JD per 1000 m3 for greenhouse vegetables declined to 5,173 JD when deductions for amortizations of the infrastructure are done. For vegetables grown under multi-spans, value of production of 4,411 JD per 1000 m3 declined to 3,786 JD after deductions for amortization of infrastructure.

Introduction of greenhouses and multi-span structures in vegetable growing in the Jordan Valley has clearly resulted in increased efficiency in the crop use of water, both in comparison to traditional citrus crops as well as open field vegetable production. Expansion of vegetable production using greenhouse technology offers an obvious opportunity for irrigation authorities to increase the value added in agriculture from the limited water resources available. Farmers in the valley should be encouraged to shift vegetable production from open fields to greenhouses, and every year more and more farmers are doing so. Irrigation officers also report that some citrus farmers have taken the decision to cut down low productivity citrus orchards and convert the land to vegetable production. Such transfers from citrus to greenhouse vegetables would result in manifold increase in crop water use efficiency; however, other factors (no only water use, but climate and soil suitability, marketability season) should be taken in account when recommending changes in cropping patterns.

The current situation for citrus should be improved by providing training for farm labor, managers, and owners, as well as extension agents on farm practices in citrus management, i.e. pruning, weed and pest control, fertigation, irrigation scheduling, and post-harvest technologies like: harvesting, grading, cooling, waxing, and packing.

Identifying what steps irrigation and agricultural authorities might adopt in order to encourage farmers to shift water use from low productivity crops and farming system to high productivity uses is beyond the scope of this modest repot.

Conclusions and Recommendations

1.- This revised analysis of crop water use efficiency in the Jordan Valley basically confirms and validates preliminary findings of an earlier study using the KAFA'A farm survey. Measuring efficiency in terms of value of production per unit of irrigation water, vegetable crops consistently yield higher values than citrus crops and/or bananas. The value of production per unit of water is also highest in the Center Jordan Valley, where vegetables predominate, and lower in the North where citrus crops predominate. Feasibility studies for production of alternative crops for each of the J.V. areas (North, Center, South and Southern Ghors) should be performed before recommendations on changes on cropping patterns are made.

2.- It should be noted that while JVA is mandated to manage and distribute irrigation water for agriculture in the Jordan Valley and Southern Ghors, the constant shortage of water (mostly from spring to fall) in the country, renders JVA short of meeting the water deliveries for crops water requirements in the farms.

3.- In this new analysis crop water allocations needs has been estimated based on the Jordan Valley Authority time-specific schedules of irrigation water delivery for the three zones in the valley, separately for bananas, citrus, and vegetable crops.

4.- This analysis also incorporates the contributions made by rainfall during the winter season to reduce the allocation needs for irrigation water from JVA. Winter vegetable crops grown under greenhouses do not benefit from rainfall, but citrus orchards and other open-field crops have their water allocation needs reduced according to the effective precipitation per month in each specific zone.

5.- Also disaggregated the vegetable crops according to the farming system, to distinguish between greenhouse vegetable production and vegetable grown in open fields or simple small plastic tunnels.

6.- Bananas generate higher value per dunum (over 1,000 JD) than citrus (nearly 500 JD) and vegetables as a group (about 600 JD). When vegetables are disaggregated, the value of production of open field vegetables drops to less than 350 JD per dunum and for greenhouse vegetables rises to about 2,000 JD per dunum.

7.- Bananas also need more water per dunum (over 1,400 m3) than citrus (under 800 m3). Open field vegetables water needs are less than 250 m3 per dunum, after allowing for rainfall, because they are on the ground only a few months during the cooler part of the year. Greenhouse vegetables need over 400 m3 per dunum because they do not benefit from rain and stay on the ground longer.

8.- Crop water use efficiency measured as value of production per 1000 m3 of water is highest for greenhouse vegetables (over 5,000 JD) while for open-field vegetables is about 1,500 JD. Bananas generate about 700 JD per 1000 m3 of irrigation water, more than citrus crops as a group which generate over 600 JD per 1000 m3.

9.- Taking into account the high initial investment cost required by greenhouse vegetables significantly reduced their values for returns on water. Accounting for establishment costs of tree crops also affected the returns per unit of water of citrus and bananas. However, the overall relative magnitudes of returns per 1000 m3 were not appreciably affected by the introduction of deductions for amortization of initial investment requirements (See Figure 16-f).

10.- There is ample scope for introduction of water saving and yield enhancement technologies to raise the productivity of irrigation water. Production of bananas under artificial shade (mesh), for example, is reported to increase yields and reduce water consumption significantly. Citrus yields and quality of fruit can also be enhanced through improved production methods and shifting trees from low value fruits (clementines, for example) to high value fruits (navel oranges, for example).

11.- Expansion during the past decade of vegetable production under plastic houses has resulted in a major jump in productivity per unit of water. There is ample potential for expansion of greenhouse production in the Jordan Valley because at present they occupy less than 12 percent of the vegetable crop area in the valley. KAFA'A might focus attention on promoting the adoption of greenhouse technology among vegetable farmers.

12.- This water-use analysis is based on gross value of production estimates derived from the farm survey. A more rigorous economic analysis requires better consideration of the structure of production costs and initial investments for each major crop in the Valley. At this stage it is difficult to make farm level specific recommendations because of lack of better understanding of the profitability of different crops and how it might be affected by alternative interventions. KAFA'A might dedicate some effort and resources to filling this void, carrying out a brief crop budget survey to determine the structure of production costs and revenues.

13.- This study also found a large discrepancy between irrigation water allocation needs, as estimated from JVA water schedules, and actual water billings to each farm in the survey sample. This poor correspondence between water schedules by crop and water bills indicate that either water deliveries do not match the cropping patterns of farms or that the billing procedures do not accurately reflect actual water deliveries, or both. A more in-depth analysis about the weak association between water bills/deliveries and farm water needs is warranted to identify where the discrepancy arises.

14.- Preliminary analysis suggests that citrus farms are getting less water (as shown in their bills) than their estimated allocation needs. By contrast, a large proportion of vegetable farms are getting more water (and being billed accordingly) than what they need based on their crop pattern. In either case, there is a need to reach a better match between how much irrigation water individual farms need and what they get. KAFA'A efforts to encourage movement toward this goal are recommended.

15.- There might be a great opportunity for higher water productivity and efficiency among vegetable farmers in the Jordan Valley. One possible reason why vegetable farmers use more water than they need is that they neglect to turn off the FTA valves once they get what they need. Without water flow meters being used to measure farm water intakes, farmers do not benefit from turning off the valves or otherwise saving water. A demonstration trial for a few months is suggested to determine how much farmers adjust irrigation water consumption when presented with tangible benefits for water savings. Such a trial might provide basis for estimating a demand schedule for irrigation water and potential gains from introducing market elements in water use.

16.- A few citrus farmers are reported to have taken the decision to cut down orchards and switch their land to vegetable production instead. From the above analysis there are substantial gains in productivity of water from transferring cropland from citrus to vegetables. There are many potential inducements that agricultural and water authorities might adopt to encourage farmers to make this switch. KAFA'A might identify what are the most significant impediments preventing citrus farmers to take this decision or to introduce higher yielding technologies.

17.- Better billing procedures for irrigation water could contribute greatly to increase overall water use efficiency. At current low rates (8 fils per m3 for the first 2,500 m3) the cost of water represents a tiny percentage of the value of the crop (A citrus farmer using 1000 m3 per year spends 8 JD per dunum for water, barely 1.6 percent of an

estimated revenue of about 500 JD). Investments in water-saving methods and equipment will not pay off at those rates.

18.- In the highlands, by contrast, where farmers pump water from deep underground, the authorities reportedly allow farmers to pump up to a certain volume at no charge, but additional water beyond that threshold carries a charge of 350 fils per m3; as a result, highland farmers are more mindful in their water use. KAFA'A and JVA might explore the possible adoption of a similar structure of water rates for farms in the Jordan Valley. Such dual rate schedule (low rate for base volume and high rate for extra water) could encourage Jordan Valley farmers to economize water without increasing actual payments for water.

Table 15. Deductions for Amortization of Initial Cost of Investments for Greenhouses and Establishment of Citrus Orchards.

Table 15. Deductions for Amortization of Initial Cost of Investments for Greenhouses and Establishment of Citrus Orchards

12% rate of interest

Cost of Greenhouse for Vegetables in 2002-2003

1,000	Initial cost of metal framework for greenhouses in 2002-2003
10	years to amortize
($176.98)	annual amortization payment for metal frames
200	Initial cost of plastic covers for greenhouses in 2002-2003
3	years to amoritize plastic covers
($83.27)	annual amortization payment for plastic covers
($260)	total annual amortization for greenhouses

Cost of Greenhouse for Vegetables in 2004-2005

1,300	Initial cost of metal framework for greenhouses in 2004-2005
($230.08)	annual amortization payment for metal frames
300	Initial cost of plastic covers for greenhouses in 2004-2005
($124.90)	annual amortization payment for plastic covers
($354.98)	Total annual amortization for greenhouses

Cost of Establishing a Citrus Orchard

	Outlays	Cumulative with interest
Year 1	**303**	
Year 2	**114**	**453**
Year 3	**114**	**622**
Year 4	**114**	**810**
Year 5		**908**

20	Years to amortize initial investment
($122)	Annual amortization payment for establishment cost

Cost of Establishing a Banana Field

483	Initial cost of establishing a field of bananas
10	years to amortize establishment cost
($85)	Annual amortization for establishment cost of bananas
